## Abstract

**Background:** Blood biomarkers showed some associations with mental health conditions . However, they remain inconclusive in predicting psychiatric disorders and suicide attempts. Identification of peripheral blood biomarkers for suicide prediction could enable  early preventive measures as they are cheap and easy to measure.

**Objectives:** We aim to compare blood biomarkers between people who have attempted suicide and who have psychiatric disorders.

**Methods:** Data was collected for this cross-sectional study between July 2021 and November 2023 from 55 hospitalised patients categorised into two groups – suicide attempt (n=29) and psychiatric disorder (n=26). We measured the complete blood count and C-reactive protein (CRP).All statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS) version 25 and were tested using a two-sided test, and a p-value of <0.05 was considered statistically significant.

**Results:** The mean age of the participants was 26.1 (±10.0) years which was significantly lower for people with suicide attempts than for those with psychiatric disorders. The mean CRP level (p=0.011), total leukocyte count (p=0.024), neutrophil (p=0.002), and neutrophil-to-lymphocyte ratio (NLR, p=0.002) were significantly higher among people with suicide attempts, whereas the lymphocyte (p=0.002) and monocyte (0.029) were significantly higher among psychiatric patients.

**Conclusion:** The findings showed NLR and CRP were more prominent blood biomarkers in suicide attempts than in psychiatric patients. However, due to the small sample size, caution is required when generalising the study results.

## INTRODUCTION

Suicide is a global public health problem. According to the latest estimates from the World Health Organization (WHO), more than 720,000 people die by suicide in a year (WHO, 2025). Suicide is affected by multiple factors such as biological factors (genes), environmental factors, socio-cultural factors, religious factors, legal factors, and generally with complex interactions among several factors. Among the risk factors, psychiatric disorders are an important factor affecting suicidal behaviour (Zalsman et al., 2016). However, clear neurobiological explanations of suicidal behaviours are yet limited (Gibbs et al., 2016). Previous studies identified that low-grade systemic inflammation was associated with suicidal behaviour and psychiatric disorders, especially psychoses and mood disorders (Bhikram and Sandor, 2022; Zheng et al., 2022; Cakir et al., 2015; Gibbs et al., 2016; Batty et al., 2016).

Finding peripheral biomarkers of chronic inflammation may enable early prevention i in mental health and suicidology (Ganança et al., 2016). Studies also found that blood biomarkers like neutrophil-to-lymphocyte ratio (NLR), monocyte-to-lymphocyte ratio (MLR), platelet-to-lymphocyte ratio (PLR), and C-reactive protein (CRP) have been associated with non-suicidal self-injury (NSSI) and suicidal behaviour (Bhikram and Sandor, 2022; Zheng et al., 2022; Arafat et al., 2021a,b; Brundin et al., 2017; Courtet et al., 2015; Arafat and Kar, 2021; Velasco et al., 2020; Ekinci and Ekinci, 2017; Brinn and Stone, 2020; Ninla-Aesong et al., 2024). These biomarkers also vary based on the method of suicide attempts, where the markers were higher in hanging than overdose (Arafat et al., 2021a), violent and nonviolent methods (Orum et al., 2018). One study found a higher presence of the NLR and other biomarkers among patients with depression than those with suicide attempts. However, the differences were not statistically significant (Gundogdu Meydaneri and Meydaneri, 2018). Another study reported higher levels of NLR and CRP among depressed patients with suicide attempts (Kumar et al., 2021) and patients with depression (Uma et al., 2022) than normal healthy controls. Velasco et al., (2020) found a significant rise in NLR in suicide attempts than in non-suicidal depressive patients, and NLR was associated with suicide attempts after controlling for age, sex and depression. It indicates NLR could be a precise biomarker of suicide attempts in psychiatric disorders.

However, currently, there is no reliable biomarker to predict suicide attempts (Morena et al., 2024). Replicative studies across cultures and countries are needed to identify an easily measurable and reliable blood biomarker for suicide attempts. Therefore, we aimed to determine and compare the blood biomarkers between hospitalised people with suicide attempts and psychiatric disorders.

## METHODS

### Data collection

This was a cross-sectional comparative study. Data was collected between July 2021 and November 2023 from 55 hospitalised patients at the psychiatry department of a tertiary care hospital in Dhaka. Among the participants, 29 were admitted with immediate non-fatal suicide attempts and the other 26 patients were admitted due to mental disorders.

We measured the complete blood count (CBC) and CRP from the blood sample. We considered hospitalised patients with a non-fatal suicide attempt within the last 48 hours and psychiatric patients who were not manageable at home and needed hospitalisation. The blood sample was collected within a day of hospitalisation.

### Laboratory measurement and values

An automated haematology analyser (XT-2000 I, SYSMEX, Japan) analysed the blood sample to determine the outcome variables of the blood profile. An automated biochemistry analyser, cobas c311 (Roche-Hitachi, Japan), was utilised to determine the CRP values. The reference values of the parameters are mentioned here. Leukocyte/white blood Cell (WBC) 4000-11000/µL, neutrophil 40-80%, lymphocyte 20-40%, monocyte 1-6%, platelet 150,000-450,000/µL, and CRP <6 mg/L. We calculated NLR, MLR and PLR from the values of neutrophils, lymphocytes and monocytes.

### Data analysis

All statistical analyses were performed using SPSS version 25. Frequencies and percentages were used to summarise the basic characteristics and biochemical markers of the study sample. Means and standard deviations (SDs) were calculated

for the continuous variables. We used the chi-square test of independence to determine the bivariate associations between the categorical variables. Fisher's exact test was conducted for those categorical variables that had an expected frequency of less than 5 observations in a cell. We used an independent samples t-test to ascertain the bivariate associations between the continuous variables. All statistics were tested using a two-sided test, and a $p$-value of <0.05 was considered statistically significant.

### Ethical approval

The ethical approval for this study was obtained from the ethical review committee of Enam Medical College (EMC/ERC/2020/08-1). Samples were collected after securing written informed consent from the adult patients and the legal guardians of adolescents.

## RESULTS

### Demographic characteristics

The mean age of the participants was 26.1 (±10.0) years, which was significantly lower for people with a suicide attempt than for those with psychiatric disorders (p=0.007, independent samples t-test, Table 1). The majority of the participants were females (61.8%), age between 19 to 35 years, had secondary education (49.1%), were students (30.9%), were married (45.5%), lived semi-urban (70.9%) and had a nuclear family (69.1%) (Table 1). The proportion of adolescents was higher in the suicide attempt group than in psychiatric patients (41.4 versus 19.2%), whereas low academic attainment was noted among psychiatric patients. Suicide attempts were higher among students and unmarried people. However, these differences were not statistically significant.

Table 1. Sociodemographic characteristics.

| Variable | Suicide attempt (n=29) | Psychiatric disorder (n=26) | Total (n=55) |
|---|---|---|---|
| **Sex** | n (%) | n (%) | n (%) |
| Male | 11 (37.9) | 10 (38.5) | 21 (38.2) |
| Female | 18 (62.1) | 16 (61.5) | 34 (61.8) |
| Age mean (SD) | 22.7 (8.3) | 29.9 (10.7) | 26.1 (10.0) |
| **Age group** | | | |
| ≤18 years | 12 (41.4) | 5 (19.2) | 17 (30.9) |
| 19 to 35 years | 15 (51.7) | 15 (57.7) | 30 (54.5) |
| >35 years | 2 (6.9) | 6 (23.1) | 8 (14.5) |
| **Education level** | | | |
| Illiterate/primary | 8 (27.6) | 14 (53.8) | 22 (40.0) |
| Secondary/higher secondary | 19 (65.5) | 8 (30.8) | 27 (49.1) |
| Bachelor's degree and above | 2 (6.9) | 4 (15.4) | 6 (10.9) |
| **Occupation** | | | |
| Housewife | 7 (24.1) | 9 (34.6) | 16 (29.1) |
| Student | 12 (41.4) | 5 (19.2) | 17 (30.9) |
| Employed | 7 (24.1) | 4 (15.4) | 11 (20.0) |
| Unemployed | 3 (10.3) | 8 (30.8) | 11 (20.0) |
| **Marital status** | | | |
| Married | 10 (34.5) | 15 (57.7) | 25 (45.5) |
| Unmarried | 16 (55.2) | 8 (30.8) | 24 (43.6) |
| Divorced/widowed/separated | 3 (10.3) | 3 (11.5) | 6 (10.9) |

| Variable | Suicide attempt (n=29) | Psychiatric disorder (n=26) | Total (n=55) |
|---|---|---|---|
| Place of residence (assessed subjectively based on local understanding) | | | |
| Urban | 3 (10.3) | 7 (26.9) | 10 (18.2) |
| Semi-urban | 23 (79.3) | 16 (61.5) | 39 (70.9) |
| Rural | 3 (10.3) | 3 (11.5) | 6 (10.9) |

| Non-smoker | 20 (69.0) | 18 (69.2) | 38 (69.1) |

*Biomarkers*

The mean CRP level was significantly higher among people with suicide attempts (p=0.011). The mean CRP was 17.9 in suicide attempts and 3.30 in psychiatric patients (Table 2). The total WBC count (p=0.024), neutrophil (p=0.002), and NLR (p=0.002) were significantly higher among people with suicide attempts. Lymphocyte (p=0.002) and monocyte (0.029) were significantly higher among psychiatric patients (Table 2). No significant associations were found between the two groups in the case of MLR (p=0.2) and PLR (p=0.1). A comparison with normal values of blood biomarkers between the two groups revealed that CRP (p=0.013), WBC count (p=0.004), and proportion of neutrophil (p=0.027) were significantly increased, whereas lymphocyte (p=0.006) significantly decreased than the normal values among the people with suicide attempts (Table 3). No significant change was noted in platelet count and monocyte proportion (Table 3).

Table 2. Comparison of blood biomarkers between suicide attempts and psychiatric disorders measured by independent samples t-test

| Variable | Suicide attempt (n=29) | Psychiatric disorder (n=26) | P value |
|---|---|---|---|
| | Mean (SD) | Mean (SD) | |
| CRP‡ (mg/L) | 17.9 (27.2)‡ | 3.3 (3.7) | 0.010 |

## DISCUSSION

### *Variations in blood biomarkers in the two groups*

The mean age was significantly lower for people with suicide attempts than for those with psychiatric disorders (p=.007), and the proportion of adolescents was higher in the suicide attempt group than in psychiatric patients. The mean CRP level (p=0.01), total WBC count (p=0.02), neutrophil (p=0.002), and NLR (p=0.002) were significantly higher among people with suicide attempts, whereas the lymphocyte was significantly higher (p=0.002) among psychiatric patients.

The CRP (p=0.013), WBC count (p=0.004), and proportion of neutrophil (p=0.027) were significantly increased, whereas lymphocyte (p=0.006) significantly decreased from the normal values among the people with suicide attempts. No significant change was noted in platelet count and the monocyte proportion.

The NLR has shown potential as an efficient and inexpensive biomarker indicating the presence of inflammation, as it can be obtained from routine blood counts without expensive immunoassays (Bhikram and Sandor, 2022; Velasco et al., 2020). Our findings are supported by a previous study that assessed CRP in three groups of hospitalised patients (suicide attempt, suicide ideation and psychiatric patients). It was found that CRP was raised in patients with suicidal ideation and then in patients with psychiatric disorders (Gibbs et al.,

2016). Other studies found both NLR and CRP were significantly higher among patients with suicide attempts and depression (n=40) and the healthy controls (n=40, Kumar et al., 2021), single episode, and recurrent depression (Uma et al., 2022), suicide attempt with depression and depression only (Ekinci and Ekinci, 2017). In our study, the parameters were higher among people with suicide attempts (without psychiatric illness, n=29) than among the patients with mental disorders (n=26). This finding was replicated in a study conducted by Velasco et al., (2020), where there was a significant rise in NLR in suicide attempts than non-suicidal depressive patients, indicating NLR could be a precise biomarker of suicide attempts.

Our study did not find any difference in MLR and PLR. One study found MLR and PLR were significantly higher among adolescents with mood disorders and NSSI than the non-NSSI group (Zheng et al., 2022). Another study recommended MLR as both an acute and enduring marker for suicide risk, as it is not affected by the actions of antidepressant medications (Petho et al., 2024).

### Finding implications

The findings may indicate several implications. Firstly, a low-grade inflammatory reaction may precede a suicide attempt, which may have similarities with psychiatric illness, however, with greater intensity. There may be overlaps in the molecular process of psychiatric disorders; especially depression is a major risk factor for suicide (Zalsman et al., 2016). However, further replicative studies are warranted. Additionally, the markers are non-specific without any association with a timeline which challenges the consideration of preventive measures for psychiatric disorders and suicide attempts. Further studies are warranted to ascertain the aspects precisely. Secondly, being cheap and easy to measure, blood biomarkers could be potential universal biomarkers for early prevention.

## LIMITATIONS

The study has several limitations. First, the sample size is relatively small in both groups, which may restrict the generalisation of the findings. Second, data was collected by convenient sampling, which may be a source of sampling bias. Third, data was collected from a single tertiary care hospital, which may not reflect the whole country's population and social class. Fourth, the sample was collected at a single point in time, which restricts cause-and-effect associations. Fifth, the medication, duration of illness and comorbidity of the patients were not controlled during the analysis, which can work as confounders. Sixth, we did not control the sociodemographic variables like age and gender during analysis, which may be a source of bias.

## CONCLUSION

The findings showed that NLR and CRP were more prominent peripheral blood biomarkers in suicide attempts than in psychiatric patients. The changes found in this study among the Bangladeshi sample in the peripheral blood biomarkers are consistent with those in other ethnicities. However, due to the small sample size, caution is warranted while generalising the study results. Studies assessing the cause-and-effect associations would be warranted to understand the phenomenon comprehensively. Additionally, assessment of blood biomarkers among people with suicide attempts and psychiatric disorders only may be a potential area of research.
